9.1: Estimating a Population Proportion

(confidence entruels Era proportion)

<u>Recall</u>: A *parameter* is a numerical summary of a population; a *statistic* is a numerical summary of a sample. (For example, the population mean and population standard deviation are parameters; the sample mean and sample standard deviation are statistics.)

Definition: A point estimate is the value of a statistic that estimates the value of a parameter.

<u>Definition</u>: A confidence interval for an unknown parameter is an interval of numbers generated by a point estimate for that parameter.

<u>Definition</u>: The *confidence level* (usually given as a percentage) represents how confident we are that the confidence interval contains the parameter.

If a large number of samples is obtained, and a separate point estimate and confidence interval are generated from each sample, then a 95% confidence level indicates that 95% of all these confidence intervals contain the population parameter.

A confidence interval is obtained by placing a *margin of error* on either side of the point estimate of the parameter.

In other words, the confidence interval consists of: Point estimate \pm margin of error

Point estimates for the population proportion:

The point estimate of the population proportion p is the sample proportion \hat{p} . The point estimate of the mean of the sampling distribution of the sample proportions is $\mu_{\hat{p}} = \hat{p}$. The point estimate of the standard deviation of the sampling distribution of the sample proportions is

$$\sigma_{\hat{p}} = \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}.$$

$$\zeta_{\hat{p}} = \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}.$$

 $z = \chi \pm t_{d/2}$ So, for every sample, the sample proportion will be in the center of the confidence interval. If we use *E* to indicate the margin of error, the confidence interval is $\hat{p} \pm E$, or $(\hat{p} - E, \hat{p} + E)$

If we use the sample proportion \hat{p} as a starting point, we should be able to write the confidence interval as $(\hat{p} - z_c \sigma_{\hat{p}}, \hat{p} + z_c \sigma_{\hat{p}})$, where $\sigma_{\hat{p}}$ is the standard deviation of the sampling distribution of the sample proportions, and z_c is a multiplier that tells us how many standard deviations (of the sampling distribution of the sample proportions) lie between the sample proportion \hat{p} and the edge of the confidence interval. We call this z_c the *critical value* for a *z*-score in the sampling distribution of the sample proportions.

Constructing the confidence interval for the proportion:

Procedure:

$$n\hat{p}(1-\hat{p}) > 10$$

- 1. Verify that $n(1-\hat{p}) \ge 0$ and that the sample is no more than 5% of the population.
- 2. Determine the confidence level, $1-\alpha$.
- 3. Determine the critical value $z_{\alpha/2}$ (using the standard normal table).
- 4. Use the sample proportion to estimate the standard deviation of the sampling distribution of the sample proportions:

$$\sigma_{\hat{p}} \approx \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$$
. (standard ervor)

5. Multiply the critical value $z_{\alpha/2}$ by the estimated standard deviation $\sigma_{\hat{p}} \approx \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$ to obtain the margin of error.

6. Add and subtract the margin of error from the sample proportion to obtain the lower and upper bounds of the confidence interval:

Lower bound:
$$\hat{p} - z_{\alpha/2} \cdot \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$$

Upper bound: $\hat{p} + z_{\alpha/2} \cdot \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$

Useful critical values of z:

(You can use these instead of looking in the table every time).

Confidence Level	α	Area in each tail, $\frac{\alpha}{2}$	Critical value $z_{\alpha/2}$
90%	0.10	0.05	1.645
95%	0.05	0.025	1.96
99%	0.01	0.005	2.575

Example 1: In a random sample of 537 Americans, 173 indicated that they frequently ate peanut butter. Construct and interpret the 90% and the 95% confidence intervals for the proportion of Americans who frequently eat peanut butter. 1

$$n = 537, \quad \text{Propertion of Americans who eat}$$

$$peanet \quad \text{butter} = p$$
Sample propertion: $\hat{p} = \frac{173}{537} \approx 0.322$

$$check \quad \text{normality:} \quad \text{Is } n\hat{p}(1-\hat{p}) > 10$$

$$= 537(0.322)(1-0.322)$$

$$= 537(0.322)(0.678)$$

$$\approx 117 > 10 \quad \text{Jex},$$

$$\overline{p} \approx \hat{p}(1-\hat{p}) = \sqrt{0.322(0.678)} \approx 0.020163$$

Sample size needed to estimate the population proportion within a given margin of error:

When constructing a confidence interval about the sample proportion \hat{p} , the margin of error is

$$z_{\alpha/2} \cdot \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}.$$

5

We can solve this for *n*:

In order to calculate the *n* needed, we need an estimate of the population proportion *p*. If such an estimate is available (perhaps from a prior study), we can use the above formula to calculate n. If not, we use the very conservative assumption that $\hat{p} = 0.5$, which gives us the maximum possible value for $\hat{p}(1-\hat{p})$, which is (0.5)(0.5) = 0.25.

Required sample size for estimation of the population proportion:

For a specified α associated with a confidence level, the sample size required to estimate the population proportion within a margin of error *E* is

$$n = \hat{p}(1-\hat{p})\left(\frac{z_{\alpha/2}}{E}\right)^2,$$

where \hat{p} is an estimate of the population proportion p.

If no estimate for the population proportion is available, we should use a sample size of at least

$$n = 0.25 \left(\frac{z_{\alpha/2}}{E}\right)^2.$$

In both cases, because the calculated n is considered a minimum threshold, we round the calculated value of n up to the nearest whole number *above*.

Example 2: A pollster wishes to estimate the percentage of likely voters who support Candidate A. Based on earlier polls, the pollster expects the candidate's level of support to be approximately 38%. What sample size should be obtained if the pollster wishes to estimate the candidate's support level within a margin of error of 3 percentage points, with 95% confidence?

$$\begin{aligned} \hat{p} = 0.38 & d = 0.05 = \sum_{i=15}^{2} [.96] \\ d = 0.03 \\ E = 0.03 \\ n = \hat{p} (1-\hat{p}) \left(\frac{2.025}{E}\right)^2 \\ = 0.38 (0.62) \left(\frac{(.96)}{0.03}\right)^2 \\ \approx 1005.65 = \sum_{i=16}^{10} \frac{1.96}{100} \\ = 0.65 = \sum_{i=16}^{10} \frac{1.96}{100$$

Lower bound:

$$\hat{P} - Z_{.05} \hat{P} = 0.322 - 1.645(0.020163)$$

 $= 0.288$
90% CI: (0.288, 0.355)
