# 8.1: Estimating a Population Mean

<u>Recall</u>: A *parameter* is a numerical summary of a population; a *statistic* is a numerical summary of a sample. (For example, the population mean and population standard deviation are parameters; the sample mean and sample standard deviation are statistics.)

<u>Definition</u>: A *point estimate* is the value of a statistic that estimates the value of a parameter.

Because it is usually unrealistic to measure or observe the entire population of interest, we use samples to gain information about the population. It seems reasonable to use a sample statistic to estimate a population parameter. However, we would not expect the sample statistic to exactly match the population parameter. How close should we expect them to be?

## **Confidence intervals:**

<u>Definition</u>: A confidence interval (CI) for an unknown parameter is an interval of numbers generated by a point estimate for that parameter.

<u>Definition</u>: The *confidence level* (usually given as a percentage) represents how confident we are that the confidence interval contains the parameter.

If a large number of samples is obtained, and a separate point estimate and confidence interval are generated from each sample, then a 95% confidence level indicates that 95% of all these confidence intervals contain the population parameter.

A confidence interval is obtained by placing a *margin of error* on either side of the point estimate of the parameter.

In other words, the confidence interval consists of: Point estimate  $\pm$  margin of error

## Point estimates for mean and standard deviation:

The point estimate of the population mean  $\mu$  is the sample mean  $\overline{x}$ . The point estimate of the population standard deviation  $\sigma$  is the sample standard deviation s.

So, for every sample, the sample mean will be in the center of the confidence interval. If we use *E* to indicate the margin of error, the confidence interval is  $\overline{x} \pm E$ , or  $(\overline{x} - E, \overline{x} + E)$ .

**Example 1:** Suppose (125, 138) is the 95% confidence interval for  $\mu$  generated by a sample. Find the sample mean *x* and the margin of error *E*.

<u>Recall</u>: The standard deviation of the sampling distribution of the sample means is called the *standard error*. It is calculated by dividing the population standard deviation by the square root of the sample size.

Standard error:  $\sigma_{\overline{x}} = \frac{\sigma}{\sqrt{n}}$ 

Because the margin of error on each side of x will be the same, we should be able to write the confidence interval as  $(\overline{x} - z_c \sigma_{\overline{x}}, \overline{x} + z_c \sigma_{\overline{x}})$ , where  $\sigma_{\overline{x}}$  is the standard deviation of the sampling distribution of the sample means, and  $z_c$  is a multiplier that tells us how many standard deviations (of the sampling distribution of the sample means) lie between the sample mean  $\overline{x}$  and the edge of the confidence interval. We call this  $z_c$  the *critical value* for a *z*-score in the sampling distribution of the sample means.

<u>Definition</u>:  $z_{\alpha}$  is the positive *z*-score for which the area to the right is  $\alpha$ .  $z_{\alpha/2}$  is the positive *z*-score for which the area to the right is  $\frac{\alpha}{2}$ .

Recall: From the Empirical Rule, for bell-shaped distributions, about 95% of the observations will lie within 2 standard deviations of the mean.

More exact version of this: For  $\alpha = 0.05$ , the critical value of z is  $z_{\alpha/2} = z_{.025} = 1.96$ .

Therefore, for samples of a given size, about 95% of the samples will lie within 1.96 standard errors of the mean.

Constructing a Confidence Interval (CI):

For a normally distributed variable with population standard deviation  $\sigma$ , using samples of size *n*, the confidence interval for the population mean  $\mu$  is

$$(\overline{x}-z_{\alpha/2}\sigma_{\overline{x}},\overline{x}+z_{\alpha/2}\sigma_{\overline{x}}),$$

where 
$$\sigma_{\overline{x}} = \frac{\sigma}{\sqrt{n}}$$
 and

 $z_{\alpha/2}$  is the critical value of z for the total tail area  $\alpha$  corresponding to the confidence level.

<u>Note</u>: If the variable is not normally distributed, this still applies as long as the sample is sufficiently large, generally for  $n \ge 30$ .

**Example 2:** Suppose the population standard deviation for a certain plant species' height is 4.3 cm. A sample of 42 plants of this species resulted in a mean height of 39.6 cm. Determine the 95% confidence interval for the plant species' height.
